

Diffraction and Interference: The Double Slit Experiment

Single Slit:

small slit:

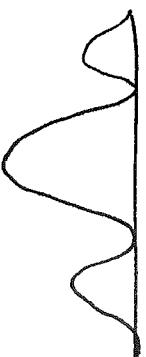

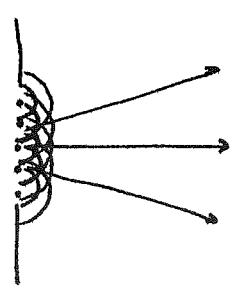

intensity
(amount of light)

what we saw
on screen

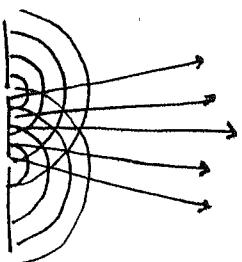

large slit

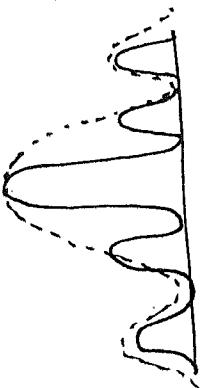

Double Slit:

two
small slits

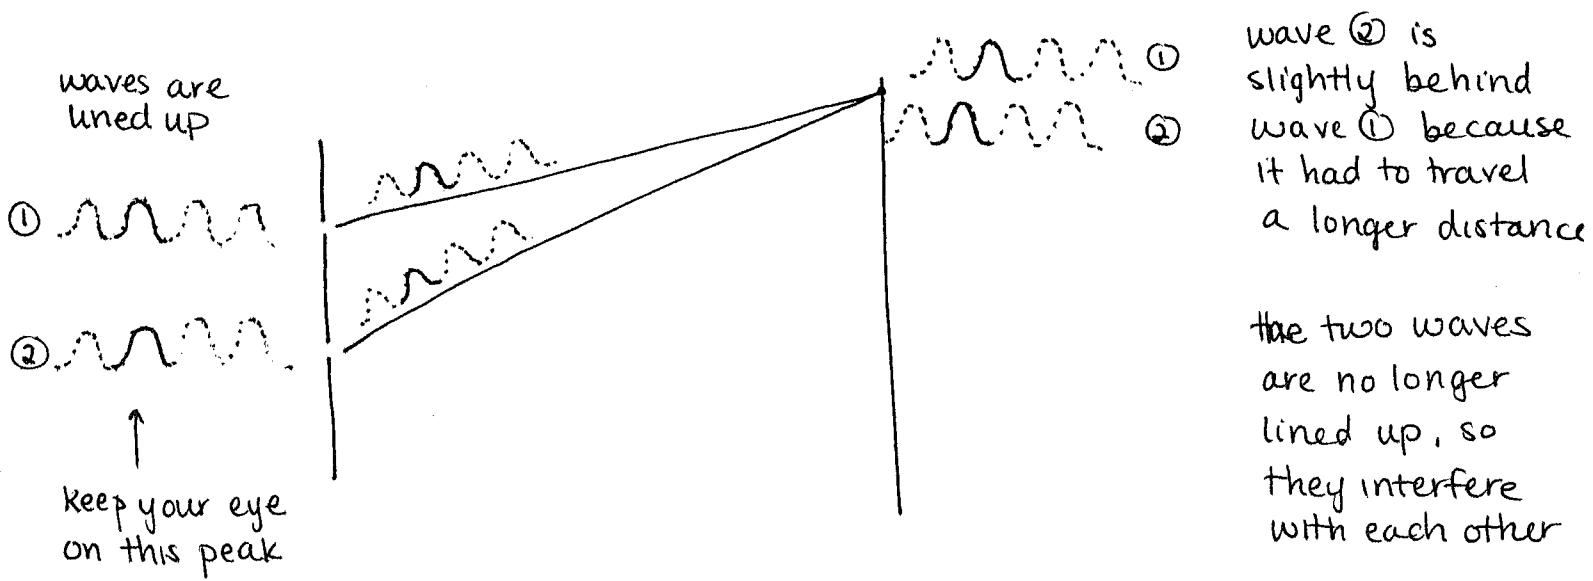

two
large slits

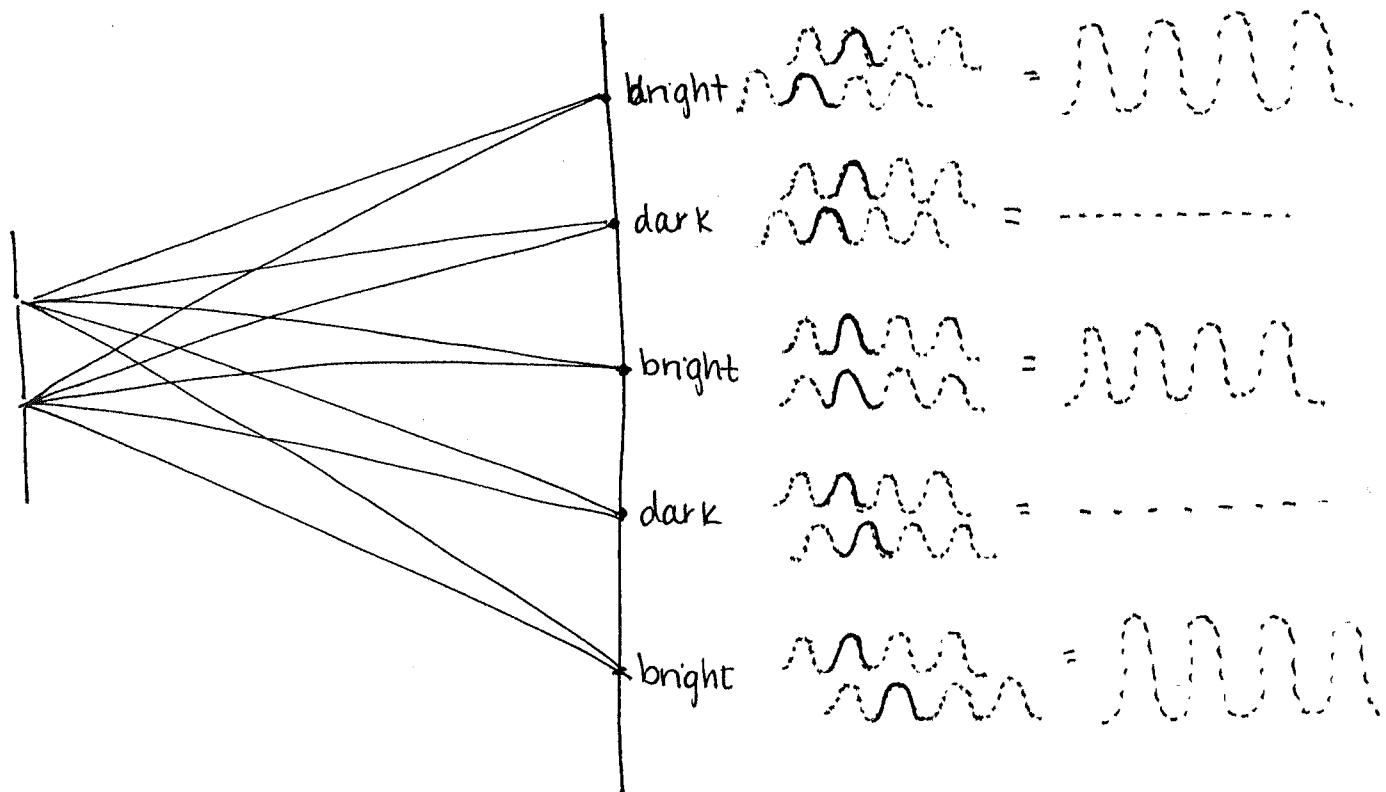

Why do we see bright and dark spots?

Consider two small slits (you could do the same calculation for a single slit) :

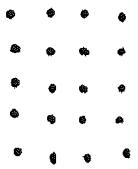

The bright and dark spots that we see depend on the interference between waves ① and ②

Crystal Diffraction

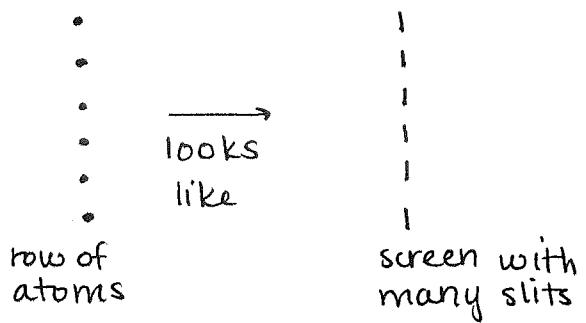

In a crystal, the atoms are spaced regularly, forming what we call a crystal lattice:

there are many different types of crystals that have different lattice structures

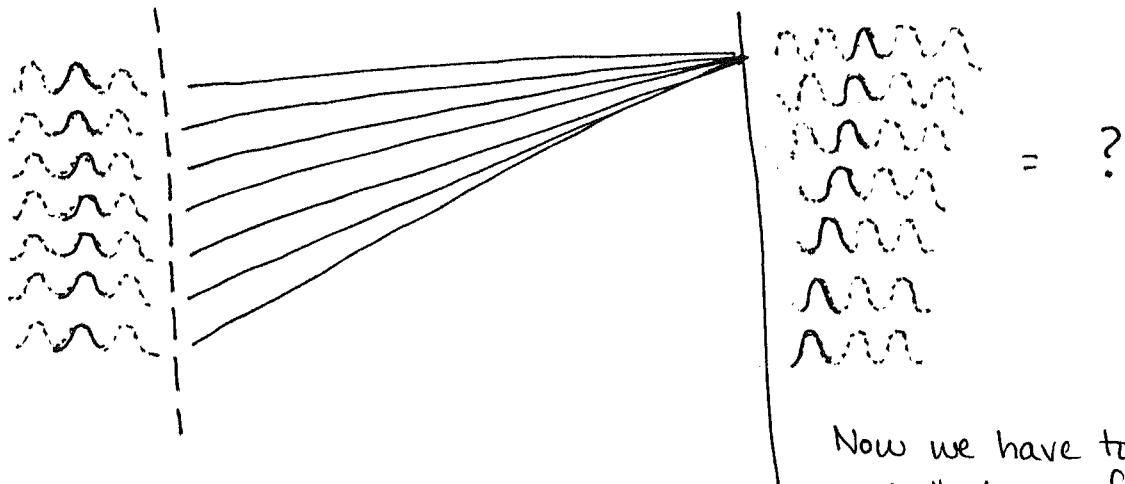

The spaces between atoms act like slits (just like the slits we used in our double-slit experiment)

Consider one row of atoms:

space between atom = slit

If we send a wave through a screen with many slits, we see diffraction and interference (just as we saw with two slits)

Now we have to add up the contributions of many waves
